14 Abstract

An increasing number of psychological experiments with children are being conducted using 15 online platforms, in part due to the COVID-19 pandemic. Individual replications have 16 compared the findings of particular experiments online and in-person, but the general effect 17 of data collection method on data collected from children is still unknown. Therefore, the 18 goal of the current meta-analysis is to estimate the average difference in effect size for 19 developmental studies conducted online compared to the same studies conducted in-person. 20 Our pre-registered analysis includes 211 effect sizes calculated from 30 papers with 3282 21 children, ranging in age from four months to six years. The mean effect size of studies 22 conducted online were slightly larger than the mean effect size of their counterparts 23 conducted in-person, a mean difference of d=-.12, but this difference was not significant, 95% CI=[-.34, .09]. We examined several potential moderators of the effect of online testing, 25 including the role of dependent measure (looking vs verbal), online study method (moderated vs unmoderated), and age, but none of these were significant. The literature to 27 date thus suggests – on average – small differences in results between in-person and online experimentation for young children.

Conducting developmental research online vs. in-person: A meta-analysis

Introduction

32

33

Developmental researchers are interested in studying children's behavior, primarily by 34 measuring their behavioral responses to experimental stimuli. Study sessions typically 35 involve visits with local families in a laboratory setting or partnering with remote sites such 36 as schools and museums. Although these interactions are a routine part of developmental 37 research, they are time-consuming for both researchers and participants. Typical studies 38 with dozens of infants or young children can require weeks or months of scheduling visits to a lab or many visits to testing sites. In-person testing also limits the participant pool to children living relatively close to the research site. Additionally, developmental research has been plagued by small, non-diverse samples even more so than research with adults due to limitations imposed by the demographics of the local population as well as the high costs of collecting data from children (Kidd & Garcia, 2022; Nielsen et al., 2017).

Prior to the rise of video chat software, there were only limited alternatives to in-person interaction for collecting experimental behavioral data from children. However, with the development of inexpensive and reliable video conferencing technology in the 2010s, new frontiers began to emerge for developmental testing. Indeed, even infants appear to follow others' gaze (Capparini et al., 2023) and establish joint attention over video chat (McClure et al., 2018). Researchers soon experimented with conducting developmental studies through video-chat platforms, which in theory broaden the pool of participants to anyone at nearly any time and location so long as they have access to internet and an internet enabled device. What began as a few research teams experimenting with online studies (e.g., Lookit: Scott & Schulz, 2017; The Child Lab: Sheskin & Keil, 2018; Pandas: Rhodes et al., 2020) quickly expanded to much of the field as researchers scrambled to conduct safe research during the

¹ Observational and survey research has long been conducted through the phone or by mail (e.g., Fenson et al., 1994); here we focus primarily on behavioral observation and experimental methods.

Covid-19 pandemic. This shift in research practices has yielded many empirical publications
where some or all of the data were collected online. In addition, there is a growing literature
on online methodology and best practices for designing such studies; we will not review this
guidance here (but see e.g., Chuey, Asaba, et al., 2021; Kominsky, Begus, et al., 2021).

Some researchers may be eager to return to in-person testing, but online research is likely here to stay and may increase in frequency as communications technologies improve and become more accessible. Online testing has immense potential to change developmental science (Sheskin et al., 2020), much as crowdsourced testing of adults has changed adult behavioral science (Buhrmester et al., 2016). This potential has yet to be fully realized, however, as researchers have yet to fully understand the strengths and weaknesses of this method, as well as how to recruit diverse populations for online studies. Despite undersampling certain populations (Lourenco & Tasimi, 2020), online studies nonetheless allow researchers to sample from a larger, broader pool of participants than ever before as access to the internet continues to increase worldwide. Large, low cost samples and remote cross-cultural research may even become a reality for developmental researchers in the coming years.

How different are the results of developmental studies conducted online to those conducted in person? Direct comparison of effects measured in both modalities is critical to answering this question. Researchers have implemented a number of paradigms online and replicated their in-person findings, but it is still largely unknown how the quality of data yielded from online developmental studies more broadly compares to those conducted in-person. Therefore, the current meta-analysis seeks to estimate effect sizes for phenomena measured with children online and for the same phenomena measured in closely-matched in-person studies. These study pairs in turn allow estimation of the average magnitude of the difference between in-person and online studies.

On the one hand, there is good reason to suspect that modality has little influence over

81

the strength of a study's effect. Fundamentally, studies conducted online and in-person utilize similar measures (e.g., looking time, verbal report) and use similar kinds of stimuli (e.g., moving objects, narrated vignettes). Additionally, experimenters still need to contend with extraneous factors like inattention, environmental distractions, and participants' mood. On the other hand, meaningful differences in online and in-person interactions could affect the outcomes of online and in-person studies, in either direction.

In principle, researchers have more control over a child's environment in-person, and in-person studies are usually less susceptible to technical problems such as lag or auditory or visual fidelity issues. Conversely, participants typically complete online studies in a more comfortable, familiar environment – their own home. Any of these factors could tip the scales, yielding larger effects in-person or online; as result, we do not make any predictions regarding the presence or direction of an effect of study modality. Further, there are many ways in which online studies vary including whether a live experimenter is present, what the dependent measure is (e.g., preferential looking vs. reaching), and the age of the sample being tested. Such factors could also influence the outcomes of online and in-person studies.

Online studies are generally conducted in one of two formats: moderated or 97 unmoderated. In moderated studies, a live experimenter guides participants through a study much like they would in-person, except online, typically via video-chat. Moderated studies gg are often operationalized as slides or videos shared with participants while the participants' 100 verbal responses or gaze is recorded. In unmoderated studies, conversely, participants 101 complete a study without the guidance of a live experimenter. Instead, researchers create a preprogrammed module that participants or their caregivers initiate and complete according 103 to instructions. Since no experimenter needs to be present and participants can participate 104 at any time they choose, unmoderated studies offer the potential for fast, inexpensive data 105 collection. However, since they lack an experimenter, participants' experiences also deviate 106 more from in-person studies compared to moderated studies that retain the same core social 107

interaction between experimenter and participant. Therefore, it is possible that data collected via unmoderated sessions is comparatively noisier since an experimenter is unable to focus children's attention or course correct like they can during a live interaction. We consider this possibility in the current meta-analysis.

Like developmental studies more broadly, online studies have also employed a number 112 of dependent measures, including verbal and looking measures. Verbal measures are typically 113 straightforward to record, while recording looking measures is more complex. Accurate 114 looking measures require precise camera positioning and coding schemes, and are thus more 115 likely to deviate from their in-person counterparts compared to studies that measure 116 children's verbal responses. To that end, automated gaze annotation is currently being 117 developed and represents an exciting future direction in online methodology (Chouinard et 118 al., 2019; see Erel et al., 2022; Steffan et al., 2024). We examine how the kind of dependent 119 measure employed (looking vs. verbal) might moderate the difference between online and 120 in-person results. 121

The final moderator we consider is participants' age. Online developmental studies 122 have sampled from a wide age range, including infants (e.g., Dillon et al., 2020), toddlers 123 (e.g., Lo et al., 2021), preschoolers (e.g., Schidelko et al., 2021), and elementary schoolers 124 (e.g., Chuey et al., 2020; Chuey, McCarthy, et al., 2021). Because online studies are often 125 conducted in the comfort of their own homes, it is possible that children of all ages might 126 benefit from this aspect of online studies. Conversely, because a child's environment is more difficult to moderate online, infant studies, which often rely on precise environmental setups, may suffer more when conducted online. In addition, as children get older they may gain 129 more experience with on-screen displays, which can contribute to their performance in online 130 studies. We test these competing age moderation hypotheses. 131

In sum, to estimate the average effect size associated with online study administration for young children, we conducted a meta-analysis of matched studies conducted online and

in-person; this includes online studies that replicated an older study conducted in-person as
well as pairs of online and in-person studies conducted in parallel. In addition, we asked
whether these differences are moderated by study format, dependent variable, or participant
age.

We stress that our goal here is not to provide a conclusive, binary answer to the 138 question of whether online and in-person studies are the same or different. Likely with 139 enough studies to analyze, we would find that there are many cases when they are similar 140 and some where they are different. Instead, our goal is to provide a best guess as to, on 141 average, how different an effect would be if it was measured online vs. in-person. Even if 142 there is some uncertainty in this estimate due to heterogeneity and the limited number of 143 available comparative studies, we believe it is an important piece of information for 144 developmental researchers as they plan the modality of their next study. 145

146 Methods

We conducted a literature search following the Preferred Reporting Items for 147 Systematic Reviews and Meta-Analyses (PRISMA) procedure (Page et al., 2021); see Figure 148 1. For each set of studies determined to be an online replication, we calculated the effect 149 size(s) and associated variance for the main effect of interest. We then conducted a series of 150 random-effects multilevel meta-regressions to estimate the effect of online data collection, as 151 well as three possible moderators (online study method, type of dependent measure, and 152 participant age). Our preregistered data selection, coding, and analysis plan can be found at 153 https://osf.io/hjbxf. The list of papers included in this meta-analysis is shown in Table 1. 154

155 Literature Search

Our goal was to find as many published and unpublished online replications of
developmental studies as possible. However, because there is no common nomenclature for
online replications and the studies themselves cover a wide range of research questions and

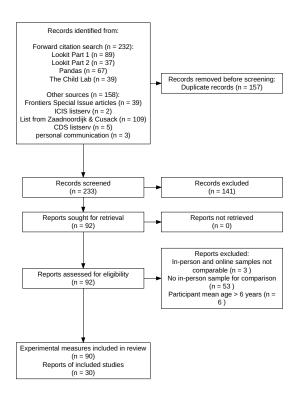

Figure 1. PRISMA plot detailing our study screening process; numerical values represent the number of papers at each stage of the systematic search.

methodologies, searching via specific terms or keywords was difficult and produced many 150 irrelevant papers; as a result, we could not conduct a completely systematic review. Instead, 160 we preregistered a forward citation search strategy based on key papers on online 161 developmental research. We used the papers that conducted initial validation of popular online testing platforms as our seeds, including Lookit (Scott et al., 2017; Scott & Schulz, 163 2017), The Child Lab (Sheskin & Keil, 2018), and Pandas (Rhodes et al., 2020). Any paper 164 that cited at least one of these papers was considered for inclusion in our meta-analysis. We 165 also considered all papers published in the Frontiers in Psychology Special Issue: Empirical Research at a Distance: New Methods for Developmental Science, which largely focused on online developmental studies and replications. Additionally, we were were pointed to 168 (Zaadnoordijk & Cusack, 2022) which contained a list of online replication papers, although 169 this yielded few additional replications. Finally, we posted a call for contributions to the 170 Cognitive Development Society (CDS) and International Congress of Infant Studies (ICIS)

listservs, two popular emailing lists frequented by developmental researchers. This call yielded several publications our initial search strategy missed, as well as six unpublished but complete online replications.

We preregistered several eligibility criteria to filter articles from our search:

- 1. The study must be experimental, where participants complete a task with a stimulus.

 This criterion precludes surveys or purely observational measures.
- 2. The studies must report two groups of children, one tested online and another tested in-person. Although the online sample must be collected by the researchers reporting the results, the in-person sample could either be collected at the same time or referenced from an existing publication.
- 3. The mean age of the sample should be under six years. This criterion limits the studies to those conducted on relatively younger children for whom online data collection methods have not been traditionally employed.
- 4. All data reported or referred to must contain codable effect sizes. Verbal comparison alone between an online or in-person study or a qualitative description of results is not enough to determine the precise effect size of interest.
- 5. Data collection for both the in-person and online sample must be complete; any incomplete or partial samples were not considered.
- 6. The online and in-person methods must be directly comparable. Some alteration to the study methods is expected when adapting an in-person study to be run online (e.g., having children refer to objects by color instead of pointing). However, we excluded any studies whose methodologies altered the nature of the task or the conclusions that could be drawn from them (e.g., changing the identity of a hidden object instead of its location in a false belief task).

Table 1

Papers used in this meta-analysis, ordered by average participant age (in months). Some papers contained both online and in-person results, others contained online replications compared to previous in-person papers. Pairs refers to the number of paired online and in-person effect sizes contributed by each paper (set). Look is whether the studies use looking, verbal, or both types of dependent measures. Mod is whether the online studies were moderated, unmoderated, or both.

Data Entry

All papers (233) yielded by our search procedure went through three rounds of 197 evaluation to determine if they met our inclusion criteria. First, we screened the titles of the 198 papers to determine whether they might include an online experiment. Those that clearly 199 did not meet one or more of our inclusion criteria were excluded from further evaluation. 200 Next, we performed a similar evaluation based on the papers' abstracts, before a final round based on the article as a whole. All remaining papers were entered into a spreadsheet that 202 coded the necessary information for calculating the size of the main effect(s) of interest and their associated variance (sample size, group means and standard deviation, and t and F 204 statistics when applicable), as well as our preregistered moderators (study modality, data 205 collection method, dependent measure, and participant age).

If a paper reported an effect size as cohen's d (referred to below as standardized mean 207 difference, SMD), we coded it directly. Otherwise, we calculated the individual effect sizes 208 for each main effect and each study (online and in-person) via reported means and standard 209 deviations, t statistic, or directly from the data if it was available using analysis scripts 210 adapted from Metalab (e.g., Bergmann et al., 2018), a repository of meta-analyses in early 211 language and cognitive development. If the main comparison was to chance performance, we 212 first calculated log odds and then converted the effect size to cohen's d via the compute.es 213 package in R (Del Re & Del Re, 2012). If a given study had multiple dependent measures or 214 central hypotheses, we calculated an effect size and associated variance for each. 215

216 Analytic Approach

231

To determine whether study modality (online or in-person) moderated the size of the
main effect of interest for each set of studies, we performed a preregistered random-effects
multilevel meta-regression using the metafor package in R (Viechtbauer, 2010). The
regression predicted individual study effect size (SMD) with study modality as a fixed effect,
modeling individual experimental effect sizes with the coefficient of interest being the study
modality predictor (online vs. in-person). As discussed above, we did not predict a direction
of effect for the study modality predictor.

Our approach focused on the study modality moderator, rather than computing an online-offline difference score for each study and estimating the size of that difference directly.

Although at a first glance this approach may seem simpler, many papers are heterogeneous and contain multiple online studies for a single given offline study, or multiple measures within the same study. In these cases, the appropriate difference was not always clear. For this reason, we chose to enter all study effects into the meta-regression and use the study modality moderator to estimate systematic modality effects.

To ensure that differences in the total number of effect sizes across studies did not bias

our analysis by overweighting studies with more measurements, we included two random 232 intercepts in our models. The first random intercept captured variation between particular 233 experiments (e.g., modeling the dependency between multiple measurements reported from a 234 single experiment). The second captured variation between groups of participants (e.g., 235 modeling the dependency between effect sizes from participants who completed a battery of 236 tasks with multiple effects of interest). 237

To determine the effect of additional moderators – online study method (moderated vs 238 unmoderated), dependent measure (looking vs verbal), and participant age - we conducted 239 three additional multilevel meta-regressions each with an additional fixed effect plus the 240 corresponding interaction with study modality. All analysis scripts were preregistered, and the code is available at https://osf.io/up6qn.

Results 243

Planned Analysis 244

245

Overall, the meta-analysis revealed a small negative, non-significant effect of online study modality, Est=-0.12, 95\% CI=[-0.34, 0.09], p=0.254. Additionally, we did not find any 246 significant effect of our preregistered moderators or any significant interactions between the 247 moderators and study modality. See Table 2 for coefficient values. Figure 2 shows the effect 248 size differences of experiments by moderators. 249

Because our meta-analysis averaged across effects from very different paradigms (which 250 could yield different effect sizes independent of the effect of testing modality), we expected substantial heterogeneity. Consistent with that expectation, all tests for residual 252 heterogeneity were highly significant (all ps < .0001). Values of τ^2 (the between-study variance in our meta-analysis) for the models were 0.23 (primary model), 0.23 (moderated vs. unmoderated model), 0.23 (looking-time model), and 0.23 (age model), respectively, 255 confirming the impression that these moderators did not reduce heterogeneity. 256

Table 2

Table of coefficients for the pre-registered models. The overall model is shown first, followed by the three models with moderators.

Coefficient	Estimate	95% CI	P-value		
Overall					
Intercept	0.75	[0.4, 1.09]	0.000		
Online	-0.12	[-0.34, 0.09]	0.254		
Looking v Verbal					
Intercept	0.65	[0.49, 0.82]	0.000		
Online	-0.15	[-0.39, 0.09]	0.227		
Verbal	-0.05	[-0.13, 0.04]	0.292		
Online:Verbal	0.04	[-0.14, 0.21]	0.693

Intercept	0.62	[0.46, 0.78]	0.000		
Online	-0.14	[-0.37, 0.08]	0.207		
Age	0.00	[-0.01, 0.01]	0.843		
Online:Age	0.00	[-0.01, 0.01]	0.526		
Moderated v Un-moderated					
Intercept	0.62	[0.47, 0.78]	0.000		
Online	-0.16	[-0.4, 0.08]	0.193		
Unmoderated	0.11	[-0.22, 0.43]	0.515		

57 Exploratory Analysis

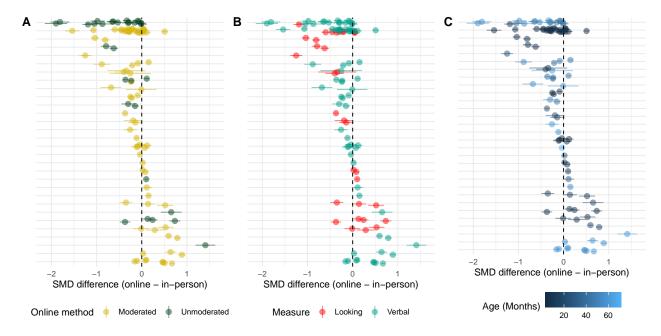

Figure 2. Forest plots of studies, sorted by difference in SMD. Each row is one study (paper or pair of papers) and contains every effect size pair contributed by that study. Each dot represents the difference between a single in-person measure and a corresponding online measure. A: Difference in SMD by study and online method (moderated vs unmoderated). B: Difference in SMD by study and measurement type (looking vs verbal). C: Difference in SMD by study and mean participant age (months).

Table 3

Mean SMD across studies by study modality, data-collection method, and type of dependent measure

Modality	Method	Measure	N (Effect-size Pairs)	SMD	95% CI
In-person	Moderated	Looking	15	0.752	[0.439, 1.065]
In-person	Moderated	Verbal	34	0.492	[0.286, 0.698]
Online	Moderated	Looking	12	0.573	[0.264, 0.882]
Online	Moderated	Verbal	27	0.372	[0.218, 0.525]
Online	Unmoderated	Looking	5	0.214	[0.062, 0.367]

Online Unmoderated Verbal 6 1.227 [0.285, 2.169]

In addition to our multi-level meta-analysis, we examined which combinations of methods and measures tended to yield the strongest and weakest effect sizes relative to their in-person counterparts. We fit a meta-analytic model containing method, response mode, and modality as well as their two- and three-way interactions, with the same random effects structure as our previous model. We cannot draw any strong conclusions about these noisy estimates due to our relatively small sample size. That said, descriptively, unmoderated online studies with looking measures were estimated to have noticeably smaller effect sizes compared to both their moderated online and in-person counterparts (See Table 3). In contrast, as estimated by this model, moderated online studies with looking and verbal measures as well as unmoderated online studies with verbal measures did not show such large differences from their in-person counterparts.

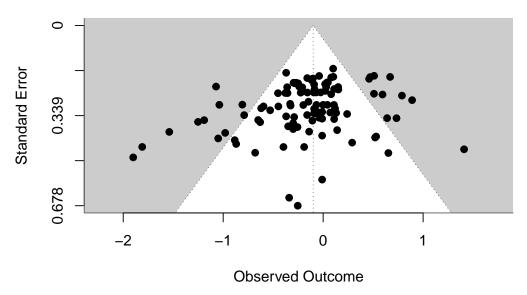

Figure 3. Funnel plot of the differences in effect size between pairs of in-person and online studies. A positive observed outcome means the online study had a larger effect size.

We also conducted an exploratory analysis of potential publication bias. It was unclear a priori how we might expect publication biases to manifest themselves, given that there is

some possibility of notoriety for either showing *or* failing to show differences between online and in-person testing. In either case our hypothesized selection process operated on the differences in effect sizes between each online and in-lab pair of samples.

For each online and in-person pair on the same study, we calculated a standard mean 274 difference in effect size between the two studies as well as the variance of this difference. The 275 resulting funnel plot is shown in Figure 3. As the difference in effect size increases, the 276 variance should also increase; however, if asymmetries are observed in this relationship (e.g., 277 a greater number of negative outcome values with low variance), effect sizes may not have 278 been uniformly reported. According to Egger's regression test for funnel plot asymmetry, a 279 common method for assessing publication bias in meta-analyses, this plot is asymmetric 280 (p=.005) and the estimated effect assuming no variance is 0.26 [-0.03, 0.55]. This analysis 281 suggests the possibility of publication bias favoring studies that have smaller effect sizes 282 online compared to in-person, signaling that perhaps online studies may have relatively 283 larger effect sizes on average compared to what has been reported. We interpret this 284 conclusion with caution, however, noting the large width of the estimated CI and the 285 relatively low power of Egger's test (Sterne et al., 2000). 286

287 Discussion

288

289

290

291

292

293

294

295

The current meta-analysis provides a birds-eye view of how developmental studies conducted online compare with closely matched counterparts conducted in-person. Our results suggest that overall, comparable studies yield relatively similar effect sizes. Even the upper end of the confidence interval for the online-offline difference estimate is still relatively small. This finding should be heartening for developmentalists interested in using online data collection.

We also examined whether modality effects emerged more substantially in particular settings, but did not find evidence for other moderators. The method of online data

collection, type of dependent measure, and participant age did not have a significant impact
on the effect of modality. Nonetheless, our lack of statistical precision, indicated by relatively
wide confidence intervals, limits our ability to draw strong conclusions about the effect of any
of our moderators. Future analysis is needed to determine the moderating effect, if any, that
these factors exercise on the outcome of developmental studies conducted online.

The current analysis is coarse-grained, considering only one particular dichotomy 301 within study modality: in-person vs online. Yet, there are many ways that developmental 302 studies can be further subdivided. For example, studies are conducted both in quiet spaces 303 (e.g., in lab, at home) and loud spaces (e.g., parks, museums), although the lack of granularity with respect to how these factors are reported in the literature renders us unable to examine them in the current meta-analysis. Therefore, online studies might over- or 306 under-perform relative to studies conducted in particular in-person locations. Our 307 moderators are also correspondingly course-grained, particularly dependent measure (looking 308 vs verbal). Because our small sample size renders our analysis underpowered to detect weaker 309 effects of moderators, the current results and their interpretation are subject to change as 310 online methods improve and comparisons to in-person studies are better understood. 311

Unmoderated studies with looking measures had the noticeably smallest effect sizes 312 relative to their in-person counterparts. This could reflect the difficulty of both collecting 313 and coding looking data online using participants' own webcams without significant 314 real-time instruction. Indeed, it is possible that effect sizes suffer without a live experimenter 315 eliciting and sustaining infants' attention or guiding parents as they position and orient their infant. However, smaller effect sizes online could instead reflect genuinely smaller effect sizes 317 of the underlying effect rather than a lack of online studies' sensitivity. Developmental research has suffered from many failures to replicate in the past, especially studies with 319 infants (e.g., Davis-Kean & Ellis, 2019), and many of the online studies in our sample were 320 conducted after their in-person counterparts, sometimes years later. Therefore, it is possible 321

that smaller online effect sizes simply represent a more accurate estimation of the true (smaller) effect rather than an effect of study modaility per se.

Unfortunately, the studies in our sample did not consistently report demographic 324 information at the level of detail necessary for investigating how participants' home 325 environment, socioeconomic status, or identity moderated the effect of study modality. 326 Although children's demographic characteristics influence their study performance no matter 327 the modality, these factors arguably stand to exert a greater influence over the outcome of 328 online studies because in-person studies standardize the study environment across 320 participants while online studies do not. Thus, the effect sizes of studies conducted online 330 are additionally at the mercy of participants' home environment, and by extension the 331 demographic factors that shape its features. 332

The composition of our sample might also bias our results. To match online and 333 in-person methods as closely as possible, we only considered direct online replications for the 334 current meta-analysis. While this approach ensures that data were collected online and 335 in-person using similar methods and procedures, it limits our sample size and may bias our 336 sample. For example, perhaps researchers disproportionately choose to conduct online 337 replications of strong or well-established effects rather than replicate more subtle, weaker 338 effects. Nonetheless, our analysis found that if publication bias exists, it likely favors stronger in-person effect sizes or non-replications among the studies we sampled. We also included an open call for unpublished data in an attempt to limit the file drawer problem (see Rosenthal, 1979).

Although developmental researchers have had decades of experience designing and running experiments in-person, most have only had a few years or less of experience developing online studies. Thus, our meta-analysis might also underestimate the potential of online research due to researcher and experimenter inexperience. Over the next several years, as developmental researchers develop expertise and experience with conducting research

online, online studies might become more accurate at capturing cognitive constructs for any 348 number of reasons, including better experimenter-participant interactions, better stimulus 349 design (see Chuey, Asaba, et al., 2021), and more accurate methods of measurement (i.e., 350 automatic looking time measures, see Erel et al., 2022). Relatedly, as new methods are 351 developed and adapted for online experiments, researchers should not take the current 352 findings as a blanket declaration that all online studies produce comparable results to their 353 in-person counterparts; some might underperform, while others might outperform. 354 Nonetheless, the current results suggest that across currently employed developmental 355 methodologies, the effect sizes of studies conducted with children online are generally 356 comparable to those conducted in-person, especially for studies utilizing verbal measures. 357

358 Conclusion

Our meta-analysis found that, across closely matched developmental studies conducted in-person and online, the size of the main effect of interest for in-person studies was similar to the effect for online studies, yielding only a small average difference between them. While our sample of studies limits the precision of our estimates, nevertheless the general similarity in outcomes for in-person and online studies with children paint an optimistic picture for online developmental research more broadly going forward.
