14 Abstract

An increasing number of psychological experiments with children are being conducted 15 using online platforms, in part due to the COVID-19 pandemic. Individual replications 16 have compared the findings of particular experiments online and in-person, but the general 17 effect of data collection method on data collected from children is still unknown. Therefore, 18 the goal of the current meta-analysis is to estimate the average difference in effect size for 19 developmental studies conducted online compared to the same studies conducted in-person. Our pre-registered analysis includes 211 effect sizes calculated from 30 papers with 3282 21 children, ranging in age from four months to six years. The mean effect size of studies conducted in-person was slightly larger than the mean effect size of their counterparts conducted online, a mean difference of d=.12, but this difference was not significant, 95% CI=[.34, -.09]. We examined several potential moderators of the effect of online testing, including the role of dependent measure (looking vs verbal), online study method 26 (moderated vs unmoderated), and age, but none of these were significant. The literature to 27 date thus suggests – on average – small differences in results between in-person and online 28 experimentation for young children. 29

Conducting developmental research online vs. in-person: A meta-analysis

Public Significance Statement

For many families, interacting with a researcher online could be their first experience
with a scientist, providing developmental science with an unprecedented outreach
opportunity. However, to ensure that online research lives up to its potential, it is
important to understand whether developmental data obtained online is comparable to
data collected in-person. The current meta-analysis finds that studies with children
conducted online produce generally similar effect sizes as those conducted in-person, which
should empower researchers to make the most of this emerging data collection and
outreach opportunity.

Introduction

Developmental researchers are interested in studying children's behavior, primarily by
measuring their behavioral responses to experimental stimuli. Study sessions typically
involve visits with local families in a laboratory setting or partnering with remote sites
such as schools and museums. Although these interactions are a routine part of
developmental research, they are time-consuming for both researchers and participants.
Typical studies with dozens of infants or young children can require weeks or months of
scheduling visits to a lab or many visits to testing sites. In-person testing also limits the
participant pool to children living relatively close to the research site. Additionally,
developmental research has been plagued by small, non-diverse samples even more so than
research with adults due to limitations imposed by the demographics of the local
population as well as the high costs of collecting data from children (Kidd & Garcia, 2022;
Nielsen, Haun, Kärtner, & Legare, 2017).

Prior to the rise of video chat software, there were only limited alternatives to in-person interaction for collecting experimental behavioral data from children. However, with the development of inexpensive and reliable video conferencing technology in the
2010s, new frontiers began to emerge for developmental testing. Researchers soon
experimented with conducting developmental studies through video-chat platforms, which
in theory broaden the pool of participants to anyone with access to internet and an
internet enabled device, at nearly any time and location. What began as a few research
teams experimenting with online studies (e.g., Lookit: Scott & Schulz, 2017; The Child
Lab: Sheskin & Keil, 2018; Pandas: Rhodes et al., 2020) quickly expanded to much of the
field as researchers scrambled to conduct safe research during the Covid-19 pandemic. This
shift in research practices has yielded many empirical publications where some or all of the
data were collected online in addition to a growing literature on online methodology and
best practices (for a recent review, see Chuey, Asaba, et al., 2021).

Some researchers may be eager to return to in-person testing, but online research is 68 likely here to stay and may increase in frequency as communications technologies improve and become more accessible. Online testing has immense potential to change 70 developmental science (Sheskin et al., 2020), much as crowdsourced testing of adults has 71 changed adult behavioral science (Buhrmester, Kwang, & Gosling, 2016). This potential has yet to be fully realized, however, as researchers have yet to fully understand the strengths and weaknesses of this method, as well as how to recruit diverse populations for online studies. Despite undersampling certain populations (Lourenco & Tasimi, 2020), online studies nonetheless allow researchers to sample from a larger, broader pool of participants than ever before as access to the internet continues to increase worldwide. Large, low cost samples and remote cross-cultural research may even become a reality for 78 developmental researchers in the coming years.

How different are the results of developmental studies conducted online to those conducted in person? Direct comparison of effects measured in both modalities is critical

¹ Observational and survey research has long been conducted through the phone or by mail (e.g., Fenson et al., 1994); here we focus primarily on behavioral observation and experimental methods.

to answering this question. Researchers have implemented a number of paradigms online
and replicated their in-person findings, but the quality of data yielded from online
developmental studies in comparison to those conducted in-person more broadly is still
largely unknown. Therefore, the current meta-analysis seeks to estimate effect sizes for
phenomena measured with children online and for the same phenomena measured in
closely-matched in-person studies. These study pairs in turn allow estimation of the
average magnitude of the difference between in-person and online studies.

On the one hand, there is good reason to suspect that modality has little influence over the strength of a study's effect. Fundamentally, studies conducted online and in-person utilize similar measures (e.g., looking time, verbal report) and use similar kinds of stimuli (e.g., moving objects, narrated vignettes). Additionally, experimenters still need to contend with extraneous factors like inattention, environmental distractions, and participants' mood. On the other hand, meaningful differences in online and in-person interactions could affect the outcomes of online and in-person studies, in either direction.

In principle, researchers have more control over a child's environment in-person, and in-person studies are usually less susceptible to technical problems such as lag or auditory or visual fidelity issues. Conversely, participants typically complete online studies in a more comfortable, familiar environment – their own home. Any of these factors could tip the scales, yielding larger effects in-person or online; as result, we do not make any predictions regarding the presence or direction of an effect of study modality. Further, online studies themselves are not a monolith, and differ in a multitude of ways including the presence of a live experimenter, dependent measure, and the age of the sample being tested. Such factors could also influence the outcomes of online and in-person studies.

Online studies are generally conducted in one of two formats: moderated or unmoderated. In moderated studies, a live experimenter guides participants through a study much like they would in-person, except online, typically via video-chat. Moderated

studies are often operationalized as slides or videos shared with participants while the 108 participants' verbal responses or looking is recorded. In unmoderated studies, conversely, 109 participants complete a study without the guidance of a live experimenter. Instead, 110 researchers create a preprogrammed module that participants or their parents initiate and 111 complete according to instructions. Since no experimenter needs to be present and 112 participants can participate at any time they choose, unmoderated studies offer the 113 potential for fast, inexpensive data collection. However, since they lack an experimenter, 114 participants' experiences also deviate more from in-person studies compared to moderated 115 studies that retain the same core social interaction between experimenter and participant. 116 Therefore, it is possible that data collected via unmoderated sessions is comparatively 117 noisier since an experimenter is unable to focus children's attention or course correct like 118 they can during a live interaction. We consider this possibility in the current meta-analysis.

Like developmental studies more broadly, online studies have also employed a number 120 of dependent measures, including verbal and looking measures. Verbal measures are 121 typically straightforward to record, while recording looking measures is more complex. 122 Accurate looking measures require precise camera positioning and coding schemes, and are 123 thus more likely to deviate from their in-person counterparts compared to studies that 124 measure children's verbal responses. To that end, automated gaze annotation is currently 125 being developed and represents an exciting future direction in online methodology (see Erel, Potter, Jaffe-Dax, Lew-Williams, & Bermano, 2022). We examine how the kind of 127 dependent measure employed (looking vs. verbal) might moderate the difference between 128 online and in-person results.

The final moderator we consider is participants' age. Online developmental studies
have sampled from a wide age range, including infants (e.g., Dillon, Izard, & Spelke, 2020),
toddlers (e.g., Lo, Rosslund, Chai, Mayor, & Kartushina, 2021), preschoolers (e.g.,
Schidelko, Schünemann, Rakoczy, & Proft, 2021), and elementary schoolers (e.g., Chuey,
Lockhart, Sheskin, & Keil, 2020; Chuey, McCarthy, et al., 2021). Because online studies

are often conducted in the comfort of their own homes, it is possible that children of all
ages might benefit from this aspect of online studies. Conversely, because a child's
environment is more difficult to moderate online, infant studies, which often rely on precise
environmental setups, may suffer more when conducted online. In addition, as children get
older they may gain more experience with on-screen displays, which can contribute to their
performance in online studies. We test these competing age moderation hypotheses.

In sum, to estimate the average effect size associated with online study administration for young children, we conducted a meta-analysis of matched studies conducted online and in-person. In addition, we asked whether these differences are moderated by study format, dependent variable, or participant age.

We stress that our goal here is not to provide a conclusive, binary answer to the question of whether online and in-person studies are the same or different. Likely with enough studies to analyze, we would find that there are many cases when they are similar and some where they are different. Instead, our goal is to provide a best guess as to, on average, how different an effect would be if it was measured online vs. in-person. Even if there is some uncertainty in this estimate due to heterogeneity and the limited number of available comparative studies, we believe it is an important piece of information for developmental researchers as they plan the modality of their next study.

153 Methods

141

142

143

We conducted a literature search following the Preferred Reporting Items for
Systematic Reviews and Meta-Analyses (PRISMA) procedure (Moher et al., 2015); see
Figure 1. For each set of studies determined to be an online replication, we calculated the
effect size(s) and associated variance for the main effect of interest. We then conducted a
series of random-effects multilevel meta-regressions to estimate the effect of online data
collection, as well as three possible moderators (online study method, type of dependent

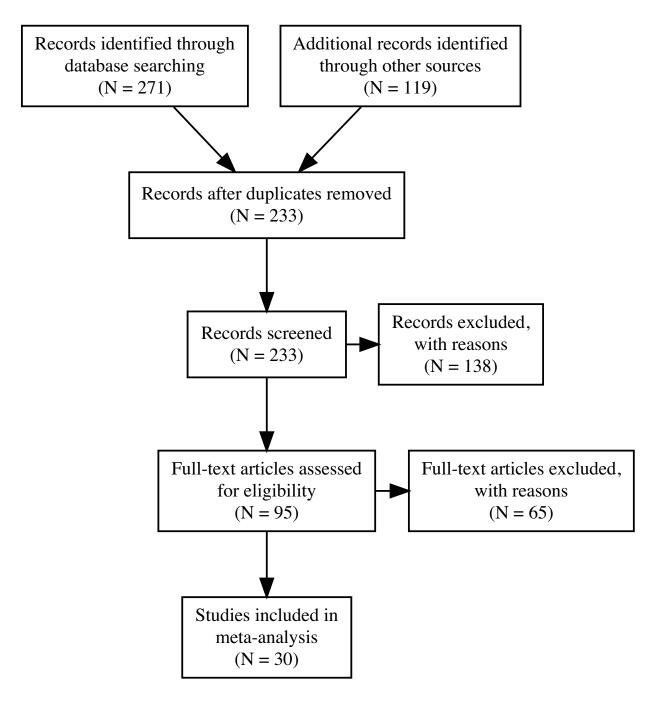

Figure 1. PRISMA plot detailing our study screening process; numerical values represent the number of papers at each stage of the review process.

measure, and participant age). Our preregistered data selection, coding, and analysis plan can be found at [anonymous for review]. The list of papers included in this meta-analysis is shown in Table 1.

163 Literature Search

180

183

184

Our goal was to find as many published and unpublished online replications of 164 developmental studies as possible. However, because there is no common nomenclature for 165 online replications and the studies themselves cover a wide range of research questions and 166 methodologies, searching via specific terms or keywords was difficult and produced many 167 irrelevant papers; as a result, we could not conduct a completely systematic review. 168 Instead, we preregistered a forward citation search strategy based on key papers on online 169 developmental research. We used the papers that conducted initial validation of popular 170 online testing platforms as our seeds, including Lookit (Scott, Chu, & Schulz, 2017; Scott 171 & Schulz, 2017), The Child Lab (Sheskin & Keil, 2018), and Pandas (Rhodes et al., 2020). 172 We also included all papers published in the Frontiers in Psychology Special Issue: 173 Empirical Research at a Distance: New Methods for Developmental Science, which largely focused on online developmental studies and replications. Finally, we posted a call for contributions to the Cognitive Development Society (CDS) and International Congress of Infant Studies (ICIS) listservs, two popular emailing lists frequented by developmental 177 researchers. This call yielded several publications our initial search strategy missed, as well 178 as six unpublished but complete online replications. 179

We preregistered several eligibility criteria to filter articles from our search:

- 1. The study must be experimental, where participants complete a task with a stimulus.

 This criterion precludes surveys or purely observational measures.
 - 2. The studies must report two groups of children, one tested online and another tested in-person. Although the online sample must be collected by the researchers reporting

- the results, the in-person sample could either be collected at the same time or referenced from an existing publication.
- 3. The mean age of the sample should be under six years. This criterion limits the studies to those conducted on relatively younger children for whom online data collection methods have not been traditionally employed.
- 4. All data reported or referred to must contain codable effect sizes. Verbal comparison alone between an online or in-person study or a qualitative description of results is not enough to determine the precise effect size of interest.
- 5. Data collection for both the in-person and online sample must be complete; any incomplete or partial samples were not considered.
- 195 6. The online and in-person methods must be directly comparable. Some alteration to
 196 the study methods is expected when adapting an in-person study to be run online
 197 (e.g., having children refer to objects by color instead of pointing). However, we
 198 excluded any studies whose methodologies altered the nature of the task or the
 199 conclusions that could be drawn from them (e.g., manipulating the identity of an
 190 object instead of its location).

Table 1

Papers used in this meta-analysis. Some papers contained both online and in-person results, others contained online replications compared to previous in-person papers. Pairs is number of online – in-person pairs contributed by each paper (set). Look is whether the studies are use looking, verbal, or both types of dependent measures. Mod is whether the online studies were moderated, unmoderated, or both. Age is the average age of the participants in months.

201 Data Entry

All papers (233) yielded by our search procedure went through three rounds of 202 evaluation to determine if they met our inclusion criteria. First, we screened the titles of 203 the papers to determine whether they might include an online experiment. Those that 204 clearly did not meet one or more of our inclusion criteria were excluded from further 205 evaluation. Next, we performed a similar evaluation based on the papers' abstracts, before 206 a final round based on the article as a whole. All remaining papers were entered into a 207 spreadsheet that coded the necessary information for us to calculate the size of the main 208 effect(s) of interest and their associated variance (sample size, group means and standard 200 deviation, and t and F statistics when applicable), as well as our preregistered moderators 210 (study modality, data collection method, dependent measure, and participant age). 211

If a paper reported an effect size as cohen's d (referred to below as standardized mean difference, SMD), we coded it directly. Otherwise, we calculated the individual effect sizes for each main effect and each study (online and in-person) via reported means and standard deviations, t statistic, or directly from the data if it was available using analysis scripts adapted from Metalab (e.g., Bergmann et al., 2018). If the main comparison was to

chance performance, we first calculated log odds and then converted the effect size to
cohen's d via the compute.es package in R (Del Re & Del Re, 2012). If a given study had
multiple dependent measures or central hypotheses, we calculated an effect size and
associated variance for each.

Analytic Approach

To determine whether study modality (online or in-person) moderated the size of the
main effect of interest for each set of studies, we performed a preregistered random-effects
multilevel meta-regression using the metafor package (Viechtbauer, 2010). The regression
predicted individual study effect size (SMD) with study modality as a fixed effect,
modeling individual experimental effect sizes with the coefficient of interest being the study
modality predictor (online vs. in-person). As discussed above, we did not predict a
direction of effect for the study modality predictor.

Our approach focused on the study modality moderator, rather than computing a
online-offline difference score for each study and estimating the size of that difference
directly. Although at a first glance this approach seems simpler, many papers are
heterogeneous and contain multiple online studies for a single given offline study, or
multiple measures within the same study. In these cases, the appropriate difference was not
always clear. For this reason, we chose to enter all study effects into the meta-regression
and use the study modality moderator to estimate systematic modality effects.

To ensure that differences in the total number of effect sizes across studies did not
bias our analysis by overweighting studies with more measurements, we included two
random intercepts in our models. The first random intercept captured variation between
particular experiments (e.g., modeling the dependency between multiple measurements
reported from a single experiment). The second captured variation between groups of
participants (e.g., modeling the dependency between effect sizes from participants who

completed a battery of tasks with multiple effects of interest).

To determine the effect of additional moderators – online study method (moderated vs unmoderated), dependent measure (looking vs verbal), and participant age - we conducted three additional multilevel meta-regressions each with an additional fixed effect plus the corresponding interaction with study modality. All analysis scripts were preregistered, and the code is available at https://osf.io/up6qn/?view_only=91ba54134dc24787b04dd8f3b3b70e1e.

249 Results

Table 3

Mean SMD across studies by study modality, data-collection method, and type of dependent measure

Modality	Method	Measure	SMD	95% CI
In-person	Moderated	Looking	0.752	[0.439, 1.065]
In-person	Moderated	Verbal	0.492	[0.286, 0.698]
Online	Moderated	Looking	0.562	[0.278, 0.847]
Online	Moderated	Verbal	0.372	[0.218, 0.525]
Online	Unmoderated	Looking	0.160	[0.034, 0.286]
Online	Unmoderated	Verbal	1.227	[0.285, 2.169]

250 Planned Analysis

Overall, the meta-analysis revealed a small negative, non-significant effect of online study modality, Est=-0.12, 95% CI=[-0.34, 0.09], p=0.254. Additionally, we did not find any significant effect of our preregistered moderators or any significant interactions

Table 2

Table of coefficients for the pre-registered models. The overall model is shown first, followed by the three models with moderators.

Coefficient	Estimate	95% CI	P-value		
Overall					
Intercept	0.75	[0.4, 1.09]	0.000		
Online	-0.12	[-0.34, 0.09]	0.254		
Looking v Verbal					
Intercept	0.65	[0.49, 0.82]	0.000		
Online	-0.15	[-0.39, 0.09]	0.227		
Verbal	-0.05	[-0.13, 0.04]	0.292		
Online:Verbal	0.04	[-0.14, 0.21]	0.693		
Age					
Intercept	0.62	[0.46, 0.78]	0.000		
Online	-0.14	[-0.37, 0.08]	0.207		
Age	0.00	[-0.01, 0.01]	0.843		
Online:Age	0.00	[-0.01, 0.01]	0.526		
Moderated v Un-moderated					
Intercept	0.62	[0.47, 0.78]	0.000		
Online	-0.16	[-0.39, 0.08]	0.184		
Unmoderated	0.12	[-0.21, 0.45]	0.467		

between the moderators and study modality. See Table 2 for coefficient values. Figure 2
shows the effect size differences of experiments by moderators.

Because our meta-analysis averaged across effects from very different paradigms

(which could yield different effect sizes independent of the effect of testing modality), we

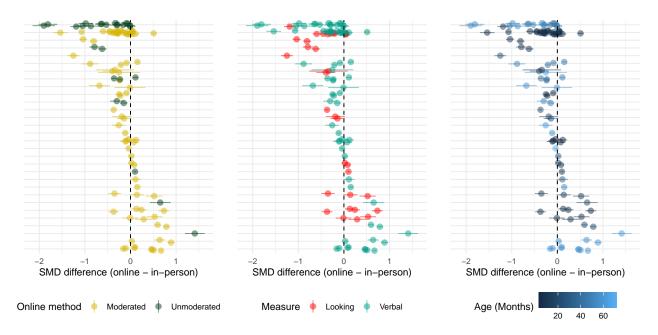

Figure 2. Forest plots of studies, sorted by difference in SMD. Each dot is the difference between and in-person measure and a corresponding online measure. Each row is one study (paper or pair of papers).

expected substantial heterogeneity. Consistent with that expectation, all tests for residual heterogeneity were highly significant (all ps < .0001). Values of τ^2 (the between-study variance in our meta-analysis) for the models were 0.23 (primary model), 0.23 (moderated vs. unmoderated model), 0.23 (looking-time model), and 0.23 (age model), respectively, confirming the impression that these moderators did not reduce heterogeneity.

263 Exploratory Analysis

In addition to our multi-level meta-analysis, we examined which combinations of
methods and measures tended to yield the strongest and weakest effect sizes relative to
their in-person counterparts. We fit a meta-analytic model containing method, response
mode, and modality as well as their two- and three-way interactions, with the same
random effects structure as our previous model. We cannot draw any strong conclusions
about these noisy estimates due to our relatively small sample size. That said,

unmoderated online studies with looking measures were estimated to have noticeably
smaller effect sizes compared to both their moderated online and in-person counterparts, to
the extent that their 95% confidence intervals do not overlap (See Table 3). In contrast, as
estimated by this model, moderated online studies with looking and verbal measures as
well as unmoderated online studies with verbal measures showed no such differences from
their in-person counterparts.

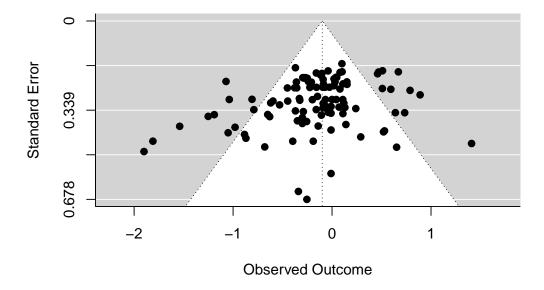

Figure 3. Funnel plot of the differences in effect size between pairs of in-person and online studies. A positive observed outcome means the online study had a large effect.

We also conducted an exploratory analysis of potential publication bias. It was unclear a priori how we might expect publication biases to manifest themselves, given that there is some possibility of notoriety for either showing or failing to show differences between online and in-person testing. In either case our hypothesized selection process operated on the differences in effect sizes between each online and in-lab pair of samples.

276

277

279

280

For each online and in-person pair on the same study, we calculated a standard mean difference in effect size between the two studies as well as the variance of this difference.

The resulting funnel plot is shown in Figure 3. According to Egger's regression test for funnel plot asymmetry, this plot is asymmetric (p=.005) and the estimated effect assuming

no variance is 0.26 [-0.03, 0.55]. This analysis suggests the possibility of publication bias favoring studies that have smaller effect sizes online compared to in-person, signaling that perhaps online studies may have relatively larger effect sizes on average compared to what has been reported. We interpret this conclusion with caution, however, noting the large width of the estimated CI and the relatively low power of Egger's test (Sterne, Gavaghan, & Egger, 2000).

291 Discussion

The current meta-analysis provides a birds-eye view of how developmental studies conducted online compare with closely matched counterparts conducted in-person. Our results suggest that overall, comparable studies yield relatively similar effect sizes. Even the upper end of the confidence interval for the online-offline difference estimate is still relatively small. This finding should be heartening for developmentalists interested in using online data collection.

We also examined whether modality effects emerged more substantially in particular settings, but did not find evidence for other moderators. The method of online data collection, type of dependent measure, and participant age did not have a significant impact on the effect of modality. Nonetheless, our lack of statistical precision, indicated by relatively wide confidence intervals, limits our ability to draw strong conclusions about the effect of any of our moderators. Future analysis is needed to determine the moderating effect, if any, that these factors exercise on the outcome of developmental studies conducted online.

The current analysis is coarse-grained, considering only one particular dichotomy
within study modality: in-person vs online. Yet, there are many ways that developmental
studies can be further subdivided. For example, studies are conducted both in quiet spaces
(e.g., in lab, at home) and loud spaces (e.g., parks, museums). Therefore, online studies

might over- or under-perform relative to studies conducted in particular in-person locations. Our moderators are also correspondingly course-grained, particularly dependent measure (looking vs verbal). Because our small sample size renders our analysis underpowered to detect weaker effects of moderators, the current results and their interpretation are subject to change as online methods improve and comparisons to in-person studies are better understood.

Unmoderated studies with looking measures had the noticeably smallest effect sizes 316 relative to their in-person counterparts. This could reflect the difficulty of both collecting 317 and coding looking data online using participants' own webcams without significant real-time instruction. However, smaller effect sizes online could instead reflect genuinely smaller effect sizes of the underlying effect rather than a lack of online studies' sensitivity. Developmental research has suffered from many failures to replicate in the past, especially 321 studies with infants (e.g., Davis-Kean & Ellis, 2019), and many of the online studies in our 322 sample were conducted after their in-person counterparts, sometimes years later. 323 Therefore, it is possible that smaller online effect sizes simply represent a more accurate 324 estimation of the true (smaller) effect rather than an effect of study modality per se. 325

The composition of our sample might also bias our results. To match online and 326 in-person methods as closely as possible, we only considered direct online replications for 327 the current meta-analysis. While this approach ensures that data were collected online and 328 in-person using similar methods and procedures, it limits our sample size and may bias our 329 sample. For example, perhaps researchers disproportionately choose to conduct online replications of strong or well-established effects rather than replicate more subtle, weaker 331 effects. Nonetheless, our analysis found that if publication bias exists, it likely favors stronger in-person effect sizes or non-replications among the studies we sampled. We also 333 included an open call for unpublished data in an attempt to limit the file drawer problem 334 (see Rosenthal, 1979). 335

Although developmental researchers have had decades of experience designing and 336 running experiments in-person, most have only had a few years or less of experience 337 developing online studies. Thus, our meta-analysis might also underestimate the potential 338 of online studies due to researcher and experimenter inexperience. Over the next several 339 years, as developmental researchers develop expertise and experience with online studies, 340 online studies might become more accurate at capturing cognitive constructs for any 341 number of reasons, including better experimenter-participant interactions, better stimulus 342 design (see Chuey, Asaba, et al., 2021), and more accurate methods of measurement (i.e., 343 automatic looking time measures, see Erel et al., 2022). Relatedly, as new methods are 344 developed and adapted for online experiments, researchers should not take the current 345 findings as a blanket declaration that all online studies produce comparable results to their 346 in-person counterparts; some might underperform, while others might outperform. Nonetheless, the current results suggest that across currently employed developmental methodologies, the effect sizes of studies conducted with children online are generally comparable to those conducted in-person, especially for studies utilizing verbal measures. 350

351 Conclusion

Our meta-analysis found that, across closely matched developmental studies
conducted in-person and online, the size of the main effect of interest for in-person studies
was similar to the effect for online studies, yielding only a small average difference between
them. While our sample of studies limits the precision of our estimates, nevertheless the
general similarity in outcomes for in-person and online studies with children paint an
optimistic picture for online developmental research more broadly going forward.
