Abstract

An increasing number of psychological experiments with children are being conducted 15 using online platforms, in part due to the COVID-19 pandemic. Individual replications 16 have compared the findings of particular experiments online and in-person, but the general 17 effect of data collection method on data collected from children is still unknown. Therefore, 18 the goal of the current meta-analysis is to estimate the average difference in effect size for 19 developmental studies conducted online compared to the same studies conducted in-person. Our pre-registered analysis includes 211 effect sizes calculated from 30 papers with 3282 21 children, ranging in age from four months to six years. The mean effect size of studies conducted online were slightly larger than the mean effect size of their counterparts conducted in-person, a mean difference of d=-.12, but this difference was not significant, 95% CI=[-.34, .09]. We examined several potential moderators of the effect of online testing, including the role of dependent measure (looking vs verbal), online study method 26 (moderated vs unmoderated), and age, but none of these were significant. The literature to 27 date thus suggests – on average – small differences in results between in-person and online 28 experimentation for young children. 29

Conducting developmental research online vs. in-person: A meta-analysis

Developmental researchers are interested in studying children's behavior, primarily by

Introduction

32

33

34

measuring their behavioral responses to experimental stimuli. Study sessions typically 35 involve visits with local families in a laboratory setting or partnering with remote sites such as schools and museums. Although these interactions are a routine part of developmental 37 research, they are time-consuming for both researchers and participants. Typical studies with dozens of infants or young children can require weeks or months of scheduling visits to a lab or many visits to testing sites. In-person testing also limits the participant pool to children living relatively close to the research site. Additionally, developmental research has been plagued by small, non-diverse samples even more so than research with adults due to limitations imposed by the demographics of the local population as well as the high costs of collecting data from children (Kidd & Garcia, 2022; Nielsen et al., 2017). Prior to the rise of video chat software, there were only limited alternatives to 45 in-person interaction for collecting experimental behavioral data from children. However, with the development of inexpensive and reliable video conferencing technology in the 2010s, new frontiers began to emerge for developmental testing. Indeed, even infants appear to follow others' gaze (Capparini et al., 2023) and establish joint attention over video chat (McClure et al., 2018). Researchers soon experimented with conducting developmental studies through video-chat platforms, which in theory broaden the pool of participants to anyone at nearly any time and location so long as they have access to internet and an internet enabled device. What began as a few research teams experimenting with online studies (e.g., Lookit: Scott & Schulz, 2017; The Child Lab: Sheskin & Keil, 2018; Pandas: Rhodes et al., 2020) quickly expanded to much of the field

<sup>&</sup>lt;sup>1</sup> Observational and survey research has long been conducted through the phone or by mail (e.g., Fenson et al., 1994); here we focus primarily on behavioral observation and experimental methods.

as researchers scrambled to conduct safe research during the Covid-19 pandemic. This shift in research practices has yielded many empirical publications where some or all of the data were collected online. In addition, there is a growing literature on online methodology and best practices for designing such studies; we will not review this guidance here (but see e.g., Chuey, Asaba, et al., 2021; Kominsky, Begus, et al., 2021).

Some researchers may be eager to return to in-person testing, but online research is
likely here to stay and may increase in frequency as communications technologies improve
and become more accessible. Online testing has immense potential to change
developmental science (Sheskin et al., 2020), much as crowdsourced testing of adults has
changed adult behavioral science (Buhrmester et al., 2016). This potential has yet to be
fully realized, however, as researchers have yet to fully understand the strengths and
weaknesses of this method, as well as how to recruit diverse populations for online studies.
Despite undersampling certain populations (Lourenco & Tasimi, 2020), online studies
nonetheless allow researchers to sample from a larger, broader pool of participants than
ever before as access to the internet continues to increase worldwide. Large, low cost
samples and remote cross-cultural research may even become a reality for developmental
researchers in the coming years.

How different are the results of developmental studies conducted online to those conducted in person? Direct comparison of effects measured in both modalities is critical to answering this question. Researchers have implemented a number of paradigms online and replicated their in-person findings, but it is still largely unknown how the quality of data yielded from online developmental studies more broadly compares to those conducted in-person. Therefore, the current meta-analysis seeks to estimate effect sizes for phenomena measured with children online and for the same phenomena measured in closely-matched in-person studies. These study pairs in turn allow estimation of the average magnitude of the difference between in-person and online studies.

On the one hand, there is good reason to suspect that modality has little influence over the strength of a study's effect. Fundamentally, studies conducted online and in-person utilize similar measures (e.g., looking time, verbal report) and use similar kinds of stimuli (e.g., moving objects, narrated vignettes). Additionally, experimenters still need to contend with extraneous factors like inattention, environmental distractions, and participants' mood. On the other hand, meaningful differences in online and in-person interactions could affect the outcomes of online and in-person studies, in either direction.

In principle, researchers have more control over a child's environment in-person, and in-person studies are usually less susceptible to technical problems such as lag or auditory or visual fidelity issues. Conversely, participants typically complete online studies in a more comfortable, familiar environment – their own home. Any of these factors could tip the scales, yielding larger effects in-person or online; as result, we do not make any predictions regarding the presence or direction of an effect of study modality. Further, there are many ways in which online studies vary including whether a live experimenter is present, what the dependent measure is (e.g., preferential looking vs. reaching), and the age of the sample being tested. Such factors could also influence the outcomes of online and in-person studies.

Online studies are generally conducted in one of two formats: moderated or 98 unmoderated. In moderated studies, a live experimenter guides participants through a study much like they would in-person, except online, typically via video-chat. Moderated 100 studies are often operationalized as slides or videos shared with participants while the 101 participants' verbal responses or gaze is recorded. In unmoderated studies, conversely, 102 participants complete a study without the guidance of a live experimenter. Instead, 103 researchers create a preprogrammed module that participants or their caregivers initiate and complete according to instructions. Since no experimenter needs to be present and 105 participants can participate at any time they choose, unmoderated studies offer the 106 potential for fast, inexpensive data collection. However, since they lack an experimenter, 107 participants' experiences also deviate more from in-person studies compared to moderated 108

studies that retain the same core social interaction between experimenter and participant.

Therefore, it is possible that data collected via unmoderated sessions is comparatively

noisier since an experimenter is unable to focus children's attention or course correct like

they can during a live interaction. We consider this possibility in the current meta-analysis.

Like developmental studies more broadly, online studies have also employed a number 113 of dependent measures, including verbal and looking measures. Verbal measures are 114 typically straightforward to record, while recording looking measures is more complex. 115 Accurate looking measures require precise camera positioning and coding schemes, and are 116 thus more likely to deviate from their in-person counterparts compared to studies that 117 measure children's verbal responses. To that end, automated gaze annotation is currently 118 being developed and represents an exciting future direction in online methodology 119 (Chouinard et al., 2019; see Erel et al., 2022; Steffan et al., 2024). We examine how the 120 kind of dependent measure employed (looking vs. verbal) might moderate the difference 121 between online and in-person results. 122

The final moderator we consider is participants' age. Online developmental studies 123 have sampled from a wide age range, including infants (e.g., Dillon et al., 2020), toddlers 124 (e.g., Lo et al., 2021), preschoolers (e.g., Schidelko et al., 2021), and elementary schoolers 125 (e.g., Chuey et al., 2020; Chuey, McCarthy, et al., 2021). Because online studies are often 126 conducted in the comfort of their own homes, it is possible that children of all ages might 127 benefit from this aspect of online studies. Conversely, because a child's environment is more difficult to moderate online, infant studies, which often rely on precise environmental 129 setups, may suffer more when conducted online. In addition, as children get older they may 130 gain more experience with on-screen displays, which can contribute to their performance in 131 online studies. We test these competing age moderation hypotheses. 132

In sum, to estimate the average effect size associated with online study administration for young children, we conducted a meta-analysis of matched studies

conducted online and in-person; this includes online studies that replicated an older study conducted in-person as well as pairs of online and in-person studies conducted in parallel. In addition, we asked whether these differences are moderated by study format, dependent variable, or participant age.

We stress that our goal here is not to provide a conclusive, binary answer to the question of whether online and in-person studies are the same or different. Likely with enough studies to analyze, we would find that there are many cases when they are similar and some where they are different. Instead, our goal is to provide a best guess as to, on average, how different an effect would be if it was measured online vs. in-person. Even if there is some uncertainty in this estimate due to heterogeneity and the limited number of available comparative studies, we believe it is an important piece of information for developmental researchers as they plan the modality of their next study.

147 Methods

We conducted a literature search following the Preferred Reporting Items for

Systematic Reviews and Meta-Analyses (PRISMA) procedure (Page et al., 2021); see

Figure 1. For each set of studies determined to be an online replication, we calculated the

effect size(s) and associated variance for the main effect of interest. We then conducted a

series of random-effects multilevel meta-regressions to estimate the effect of online data

collection, as well as three possible moderators (online study method, type of dependent

measure, and participant age). Our preregistered data selection, coding, and analysis plan

can be found at https://osf.io/hjbxf. The list of papers included in this meta-analysis is

shown in Table 1.

Identification of studies via forward citation search, Frontiers special issue, and listservs Records identified from: Forward citation search (n = 232): Lookit Part 1 (n = 89)Lookit Part 2 (n = 37)Records removed before screening: Pandas (n = 67)Duplicate records (n = 157) The Child Lab (n = 39)Records marked as ineligible by automation Other sources (n = 158): tools (n = 0)Frontiers Special Issue articles (n = 39) Records removed for other reasons (n = 0)ICIS listserv (n = 2) List from Zaadnoordijk & Cusack (n = 109) CDS listserv (n = 5)personal communication (n = 3)Records screened Records excluded (n = 233)(n = 141)Reports sought for retrieval Reports not retrieved (n = 92)(n = 0)Reports excluded: In-person and online samples not Reports assessed for eligibility comparable (n = 3)(n = 92)No in-person sample for comparison (n = 53)Participant mean age > 6 years (n = 6) Experimental measures included in review (n = 90)Reports of included studies (n = 30)

#### 57 Literature Search

177

Our goal was to find as many published and unpublished online replications of 158 developmental studies as possible. However, because there is no common nomenclature for 159 online replications and the studies themselves cover a wide range of research questions and methodologies, searching via specific terms or keywords was difficult and produced many irrelevant papers; as a result, we could not conduct a completely systematic review. Instead, we preregistered a forward citation search strategy based on key papers on online 163 developmental research. We used the papers that conducted initial validation of popular 164 online testing platforms as our seeds, including Lookit (Scott et al., 2017; Scott & Schulz, 165 2017), The Child Lab (Sheskin & Keil, 2018), and Pandas (Rhodes et al., 2020). Any 166 paper that cited at least one of these papers was considered for inclusion in our 167 meta-analysis. We also considered all papers published in the Frontiers in Psychology 168 Special Issue: Empirical Research at a Distance: New Methods for Developmental Science, 169 which largely focused on online developmental studies and replications. Additionally, we 170 were were pointed to (Zaadnoordijk & Cusack, 2022) which contained a list of online 171 replication papers, although this yielded few additional replications. Finally, we posted a 172 call for contributions to the Cognitive Development Society (CDS) and International 173 Congress of Infant Studies (ICIS) listservs, two popular emailing lists frequented by 174 developmental researchers. This call yielded several publications our initial search strategy 175 missed, as well as six unpublished but complete online replications. 176

We preregistered several eligibility criteria to filter articles from our search:

- 1. The study must be experimental, where participants complete a task with a stimulus.

  This criterion precludes surveys or purely observational measures.
- 2. The studies must report two groups of children, one tested online and another tested in-person. Although the online sample must be collected by the researchers reporting

- the results, the in-person sample could either be collected at the same time or referenced from an existing publication.
- 3. The mean age of the sample should be under six years. This criterion limits the studies to those conducted on relatively younger children for whom online data collection methods have not been traditionally employed.
- 4. All data reported or referred to must contain codable effect sizes. Verbal comparison alone between an online or in-person study or a qualitative description of results is not enough to determine the precise effect size of interest.
- 5. Data collection for both the in-person and online sample must be complete; any incomplete or partial samples were not considered.
- 192 6. The online and in-person methods must be directly comparable. Some alteration to
  193 the study methods is expected when adapting an in-person study to be run online
  194 (e.g., having children refer to objects by color instead of pointing). However, we
  195 excluded any studies whose methodologies altered the nature of the task or the
  196 conclusions that could be drawn from them (e.g., changing the identity of a hidden
  197 object instead of its location in a false belief task).

Table 1

Papers used in this meta-analysis, ordered by average participant age (in months). Some papers contained both online and in-person results, others contained online replications compared to previous in-person papers. Pairs refers to the number of paired online and in-person effect sizes contributed by each paper (set). Look is whether the studies use looking, verbal, or both types of dependent measures. Mod is whether the online studies were moderated, unmoderated, or both.

### 198 Data Entry

All papers (233) yielded by our search procedure went through three rounds of
evaluation to determine if they met our inclusion criteria. First, we screened the titles of
the papers to determine whether they might include an online experiment. Those that
clearly did not meet one or more of our inclusion criteria were excluded from further
evaluation. Next, we performed a similar evaluation based on the papers' abstracts, before
a final round based on the article as a whole. All remaining papers were entered into a
spreadsheet that coded the necessary information for calculating the size of the main
effect(s) of interest and their associated variance (sample size, group means and standard
deviation, and t and F statistics when applicable), as well as our preregistered moderators

(study modality, data collection method, dependent measure, and participant age).

If a paper reported an effect size as cohen's d (referred to below as standardized mean 209 difference, SMD), we coded it directly. Otherwise, we calculated the individual effect sizes 210 for each main effect and each study (online and in-person) via reported means and 211 standard deviations, t statistic, or directly from the data if it was available using analysis 212 scripts adapted from Metalab (e.g., Bergmann et al., 2018), a repository of meta-analyses 213 in early language and cognitive development. If the main comparison was to chance 214 performance, we first calculated log odds and then converted the effect size to cohen's d via 215 the compute.es package in R (Del Re & Del Re, 2012). If a given study had multiple 216 dependent measures or central hypotheses, we calculated an effect size and associated 217 variance for each.

## 219 Analytic Approach

To determine whether study modality (online or in-person) moderated the size of the
main effect of interest for each set of studies, we performed a preregistered random-effects
multilevel meta-regression using the metafor package in R (Viechtbauer, 2010). The
regression predicted individual study effect size (SMD) with study modality as a fixed
effect, modeling individual experimental effect sizes with the coefficient of interest being
the study modality predictor (online vs. in-person). As discussed above, we did not predict
a direction of effect for the study modality predictor.

Our approach focused on the study modality moderator, rather than computing an online-offline difference score for each study and estimating the size of that difference directly. Although at a first glance this approach may seem simpler, many papers are heterogeneous and contain multiple online studies for a single given offline study, or multiple measures within the same study. In these cases, the appropriate difference was not always clear. For this reason, we chose to enter all study effects into the meta-regression

and use the study modality moderator to estimate systematic modality effects.

To ensure that differences in the total number of effect sizes across studies did not 234 bias our analysis by overweighting studies with more measurements, we included two 235 random intercepts in our models. The first random intercept captured variation between 236 particular experiments (e.g., modeling the dependency between multiple measurements 237 reported from a single experiment). The second captured variation between groups of 238 participants (e.g., modeling the dependency between effect sizes from participants who 239 completed a battery of tasks with multiple effects of interest).

To determine the effect of additional moderators – online study method (moderated vs unmoderated), dependent measure (looking vs verbal), and participant age - we 242 conducted three additional multilevel meta-regressions each with an additional fixed effect plus the corresponding interaction with study modality. All analysis scripts were preregistered, and the code is available at https://osf.io/up6qn.

Results 246

#### Planned Analysis 247

241

243

245

Overall, the meta-analysis revealed a small negative, non-significant effect of online 248 study modality, Est=-0.12, 95\% CI=[-0.34, 0.09], p=0.254. Additionally, we did not find 249 any significant effect of our preregistered moderators or any significant interactions 250 between the moderators and study modality. See Table 2 for coefficient values. Figure 2 251 shows the effect size differences of experiments by moderators. 252

Because our meta-analysis averaged across effects from very different paradigms 253 (which could yield different effect sizes independent of the effect of testing modality), we 254 expected substantial heterogeneity. Consistent with that expectation, all tests for residual 255 heterogeneity were highly significant (all ps < .0001). Values of  $\tau^2$  (the between-study 256 variance in our meta-analysis) for the models were 0.23 (primary model), 0.23 (moderated 257

Table 2

Table of coefficients for the pre-registered models. The overall model is shown first, followed by the three models with moderators.

Coefficient	Estimate	95% CI	P-value			
Overall						
Intercept	0.75	[0.4, 1.09]	0.000			
Online	-0.12	[-0.34, 0.09]	0.254

confirming the impression that these moderators did not reduce heterogeneity.

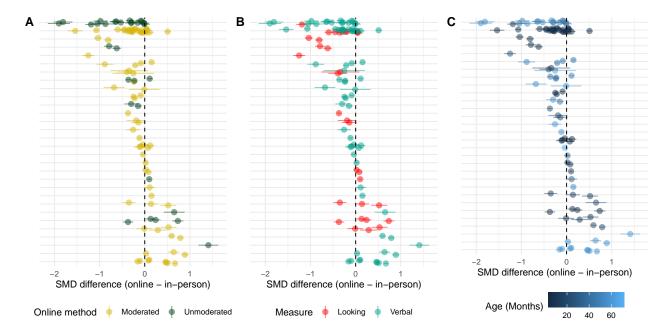

Figure 2. Forest plots of studies, sorted by difference in SMD. Each row is one study (paper or pair of papers) and contains every effect size pair contributed by that study. Each dot represents the difference between a single in-person measure and a corresponding online measure. A: Difference in SMD by study and online method (moderated vs unmoderated). B: Difference in SMD by study and measurement type (looking vs verbal). C: Difference in SMD by study and mean participant age (months).

Table 3

Mean SMD across studies by study modality, data-collection method, and type of dependent measure

Modality	Method	Measure	N (Effect-size Pairs)	SMD	95% CI
In-person	Moderated	Looking	15	0.752	[0.439, 1.065]
In-person	Moderated	Verbal	34	0.492	[0.286,0.698]
Online	Moderated	Looking	12	0.573	[0.264,  0.882]
Online	Moderated	Verbal	27	0.372	[0.218,  0.525]
Online	Unmoderated	Looking	5	0.214	[0.062,  0.367]

Online Unmoderated Verbal 6 1.227 [0.285, 2.169]

In addition to our multi-level meta-analysis, we examined which combinations of 261 methods and measures tended to yield the strongest and weakest effect sizes relative to 262 their in-person counterparts. We fit a meta-analytic model containing method, response 263 mode, and modality as well as their two- and three-way interactions, with the same 264 random effects structure as our previous model. We cannot draw any strong conclusions 265 about these noisy estimates due to our relatively small sample size. That said, 266 descriptively, unmoderated online studies with looking measures were estimated to have 267 noticeably smaller effect sizes compared to both their moderated online and in-person 268 counterparts (See Table 3). In contrast, as estimated by this model, moderated online 269 studies with looking and verbal measures as well as unmoderated online studies with verbal 270 measures did not show such large differences from their in-person counterparts. 271

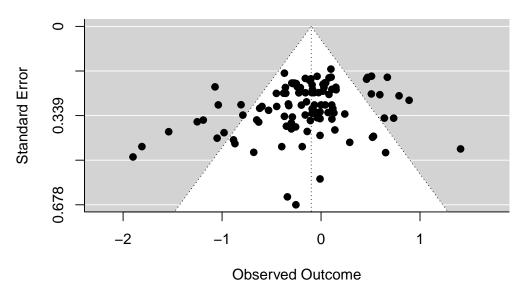

Figure 3. Funnel plot of the differences in effect size between pairs of in-person and online studies. A positive observed outcome means the online study had a larger effect size.

We also conducted an exploratory analysis of potential publication bias. It was unclear *a priori* how we might expect publication biases to manifest themselves, given that

there is some possibility of notoriety for either showing *or* failing to show differences
between online and in-person testing. In either case our hypothesized selection process
operated on the *differences* in effect sizes between each online and in-lab pair of samples.

For each online and in-person pair on the same study, we calculated a standard mean 277 difference in effect size between the two studies as well as the variance of this difference. 278 The resulting funnel plot is shown in Figure 3. As the difference in effect size increases, the 279 variance should also increase; however, if asymmetries are observed in this relationship 280 (e.g., a greater number of negative outcome values with low variance), effect sizes may not 281 have been uniformly reported. According to Egger's regression test for funnel plot 282 asymmetry, a common method for assessing publication bias in meta-analyses, this plot is 283 asymmetric (p=.005) and the estimated effect assuming no variance is 0.26 [-0.03, 0.55]. 284 This analysis suggests the possibility of publication bias favoring studies that have smaller effect sizes online compared to in-person, signaling that perhaps online studies may have relatively larger effect sizes on average compared to what has been reported. We interpret 287 this conclusion with caution, however, noting the large width of the estimated CI and the 288 relatively low power of Egger's test (Sterne et al., 2000).

290 Discussion

297

298

The current meta-analysis provides a birds-eye view of how developmental studies conducted online compare with closely matched counterparts conducted in-person. Our results suggest that overall, comparable studies yield relatively similar effect sizes. Even the upper end of the confidence interval for the online-offline difference estimate is still relatively small. This finding should be heartening for developmentalists interested in using online data collection.

We also examined whether modality effects emerged more substantially in particular settings, but did not find evidence for other moderators. The method of online data

collection, type of dependent measure, and participant age did not have a significant impact on the effect of modality. Nonetheless, our lack of statistical precision, indicated by relatively wide confidence intervals, limits our ability to draw strong conclusions about the effect of any of our moderators. Future analysis is needed to determine the moderating effect, if any, that these factors exercise on the outcome of developmental studies conducted online.

The current analysis is coarse-grained, considering only one particular dichotomy 305 within study modality: in-person vs online. Yet, there are many ways that developmental 306 studies can be further subdivided. For example, studies are conducted both in quiet spaces 307 (e.g., in lab, at home) and loud spaces (e.g., parks, museums), although the lack of 308 granularity with respect to how these factors are reported in the literature renders us 309 unable to examine them in the current meta-analysis. Therefore, online studies might over-310 or under-perform relative to studies conducted in particular in-person locations. Our 311 moderators are also correspondingly course-grained, particularly dependent measure 312 (looking vs verbal). Because our small sample size renders our analysis underpowered to 313 detect weaker effects of moderators, the current results and their interpretation are subject 314 to change as online methods improve and comparisons to in-person studies are better understood. 316

Unmoderated studies with looking measures had the noticeably smallest effect sizes 317 relative to their in-person counterparts. This could reflect the difficulty of both collecting 318 and coding looking data online using participants' own webcams without significant 319 real-time instruction. Indeed, it is possible that effect sizes suffer without a live experimenter eliciting and sustaining infants' attention or guiding parents as they position 321 and orient their infant. However, smaller effect sizes online could instead reflect genuinely smaller effect sizes of the underlying effect rather than a lack of online studies' sensitivity. 323 Developmental research has suffered from many failures to replicate in the past, especially 324 studies with infants (e.g., Davis-Kean & Ellis, 2019), and many of the online studies in our 325

sample were conducted after their in-person counterparts, sometimes years later.

Therefore, it is possible that smaller online effect sizes simply represent a more accurate estimation of the true (smaller) effect rather than an effect of study modaility per se.

Unfortunately, the studies in our sample did not consistently report demographic 329 information at the level of detail necessary for investigating how participants' home 330 environment, socioeconomic status, or identity moderated the effect of study modality. 331 Although children's demographic characteristics influence their study performance no 332 matter the modality, these factors arguably stand to exert a greater influence over the 333 outcome of online studies because in-person studies standardize the study environment 334 across participants while online studies do not. Thus, the effect sizes of studies conducted 335 online are additionally at the mercy of participants' home environment, and by extension 336 the demographic factors that shape its features. 337

The composition of our sample might also bias our results. To match online and in-person methods as closely as possible, we only considered direct online replications for the current meta-analysis. While this approach ensures that data were collected online and in-person using similar methods and procedures, it limits our sample size and may bias our sample. For example, perhaps researchers disproportionately choose to conduct online replications of strong or well-established effects rather than replicate more subtle, weaker effects. Nonetheless, our analysis found that if publication bias exists, it likely favors stronger in-person effect sizes or non-replications among the studies we sampled. We also included an open call for unpublished data in an attempt to limit the file drawer problem (see Rosenthal, 1979).

Although developmental researchers have had decades of experience designing and running experiments in-person, most have only had a few years or less of experience developing online studies. Thus, our meta-analysis might also underestimate the potential of online research due to researcher and experimenter inexperience. Over the next several

years, as developmental researchers develop expertise and experience with conducting 352 research online, online studies might become more accurate at capturing cognitive 353 constructs for any number of reasons, including better experimenter-participant 354 interactions, better stimulus design (see Chuey, Asaba, et al., 2021), and more accurate 355 methods of measurement (i.e., automatic looking time measures, see Erel et al., 2022). 356 Relatedly, as new methods are developed and adapted for online experiments, researchers 357 should not take the current findings as a blanket declaration that all online studies produce 358 comparable results to their in-person counterparts; some might underperform, while others 359 might outperform. Nonetheless, the current results suggest that across currently employed 360 developmental methodologies, the effect sizes of studies conducted with children online are 361 generally comparable to those conducted in-person, especially for studies utilizing verbal 362 measures.

364 Conclusion

Our meta-analysis found that, across closely matched developmental studies
conducted in-person and online, the size of the main effect of interest for in-person studies
was similar to the effect for online studies, yielding only a small average difference between
them. While our sample of studies limits the precision of our estimates, nevertheless the
general similarity in outcomes for in-person and online studies with children paint an
optimistic picture for online developmental research more broadly going forward.
